ABSTRACT

Left untreated or not properly managed odontogenic infection can cause spreading into facial spaces. Severe oral and maxillofacial infection can spread systemically and cause sepsis.¹ Sepsis can induce unfavorable condition for the kidney, which is Acute Kidney Injury (AKI).²,³ The aim of this paper is to report a rare case of an oral and maxillofacial infection with sepsis-induced AKI and upper airway obstruction which have high mortality rate. The standard treatment consists of proper monitoring of vital function, fluid resuscitation, drainage of accumulated purulence, empirical use of antibiotics chosen to cover the spectrum of potential pathogens until culture results are available, and supplemental oxygen.¹,⁴ This is a case report of a 48 year old female patient with oral and maxillofacial infection suffers sepsis-induced AKI and upper airway obstruction. This patient was diagnosed as right submandibular abscess which has extended into right buccal space, with sepsis, stage I AKI, and upper airway obstruction due to retropharyngeal abscess. We managed this patient with oxygenation, fluid resuscitation, antibiotics and analgesic administration, incision and drainage, and also extraction of mandibular right third molar. Tracheostomy, incision and drainage of retropharyngeal abscess were supposed to be performed by ENT department, but the patient refused. However the patient still survived. In case of oral and maxillofacial infection, the involvement of distant organ should be investigated, because this conditions result in high mortality rate. Early diagnosis and prompt treatment are important and able to lead to a better survival.
INTRODUCTION

Infection from submandibular abscess due to mandibular third molar infection can spread into retropharyngeal space through the lateral pharyngeal space which is close by. When the retropharyngeal or prevertebral fascial spaces or both are involved as a result of odontogenic infection, the patient mostly gets serious ill. The followings are the three greatest potential complications: the serious possibility of upper airway obstruction as a result of anterior displacement of the posterior pharyngeal wall into the oral pharynx; rupture of the retropharyngeal abscess, with aspiration of pus into the lungs and subsequent asphyxiation; and spread of the infection from the retropharyngeal spaces into the mediastinum, which results in severe infection in the thorax. 1,4,5,6

When a patient has extension of infection into the cervical region, the retropharyngeal space must be evaluated with lateral radiographs of the neck to determine whether the space is enlarged and thereby compromising the airway, causing upper airway obstruction. 1,3,5

Fortunately, clinically significant sepsis is rarely caused by infections in the maxillofacial region for several reasons, however mostly sepsis can be resulted from any untreated infection of the head and neck and can occur in immunodeficient patients with maxillofacial infections. The most severe manifestation of sepsis is diffuse peripheral vasodilation, which produces septic shock. The vasodilation that occurs during sepsis is believed to be caused by toxins produced by infecting organisms and release of vasoactive substances as the result of the interaction between bacterial products and infected tissues, white blood cells, and platelets. 1 The peripheral vasodilation produces a relative hypovolemia, impairing perfusion of vital organs, such as kidney. Hypoperfusion due to peripheral vasodilation may lead to AKI, this is the most common form of pre-renal AKI. Pre-renal AKI is generally reversible when renal perfusion pressure is restored. However, more severe or prolonged hypoperfusion may lead to ischemic injury, often termed Acute Tubular Necrosis (ATN). 2

As mentioned above, the infections of oral and maxillofacial originated from odontogenic infection rarely cause sepsis and inducing AKI, but in this case report we present an oral and maxillofacial infections with sepsis-induced AKI which has high mortality rate. Early diagnosis and prompt management lead to patient’s survival.

AKI is defined as any of the following conditions (not graded), increase in Scr by $\geq 0.3$ mg/dl ($\geq 26.5\mu$mol/l) within 48 hours; or increase in Scr to $\geq 1.5$ times baseline, which is known or presumed to have occurred within the prior 7 days; or urine output <0.5 ml/kg/h for 6 hours. The Etiology of AKI include pre-renal, intrinsic renal, and post-renal. Sepsis can induce pre-renal AKI following renal hypoperfusion. 3,7,8,9

AKI commonly happens with hospitalized patients and also has a poor prognosis with the mortality ranging from 10%-80% dependent upon the patient population studied. Patients who present with uncomplicated AKI, have a mortality rate of up to 10%. In contrast, patients presenting with AKI and multiorgan failure have been reported to have mortality rates over 50%. If renal replacement therapy is required, the mortality rate rises further to as high as 80%. 9

CASE REPORT

A 48 year old female patient was admitted to Hasan Sadikin Hospital referred from local hospital for oral and maxillofacial infection. She complained about pain and swelling on her right cheek since four days prior to admission. About seven days before admitted to hospital, patient complained about pain on her right most posterior mandibular tooth accompanied with fever, and then she seek for help to local dentist and was given four kinds of medicine. After taking the medicine for several days, the patient found no improvement and her right cheek swelled that the patient went to local hospital and then referred to Hasan Sadikin General hospital.

In our physical examination we found an increase in pulse rate of 102 beats/min, body temperature of 38.6°C, respiratory rate of 24 breaths/min. A slight decrease in skin turgor and inspiratory stridor were also revealed. Her conjunctiva was anemic. Neck examination revealed that the right submandible lymph node was difficult to assess due to swelling on her right submandible, other physical examinations were within normal limit. In extraoral examination we found facial asymmetry due to diffused, fluctuative, and hyperemic swelling on her right submandible which is spreading into right buccal, accompanied with pain on pressure. Local temperature was warm on this swelling (Figure 1).
Figure 1. Clinical appearance patient with right submandible abscess which spreads into right buccal space.

Patient’s mouth opening was about 1.5 cm. Intraoral examination revealed spontaneous pus drainage at mandibular right third molar region and profound caries within this tooth, plaque and calculus were also found around this tooth and neighbouring teeth, we also found dry labial mucosa (Figure 2).

Figure 2. Intraoral photograph of this patient, also showing dry labial mucosa.

This patient was diagnosed as right submandibular abscess which has spreaded into right buccal space, with sepsis, stage I AKI and upper airway obstruction due to retropharyngeal abscess. We managed this patient with oxygenation via nasal canule 3L/mnt, fluid resuscitation with moderate rehydration by 132 drops/mnt of crystalloid for the first 6 hours followed by urinary catheter insertion for monitoring urine output, pus aspirations, administration of 1 gr of ceftriaxone, 500 mg of metronidazole, 50 mg of ranitidine, 30 mg of ketorolac intravenously, and laboratory examination including culture, resistance and sensitivity test, radiograph examination, consultation to ENT and internal medicine department. The interpretation of AP and lateral neck soft tissue radiographs showed narrowing of laryngeal and pharyngeal airway column, widening of retropharyngeal and retrolaryngeal spaces, also an appearance of opaque shadow with soft tissue density at the right side of the neck with calcification. These neck soft tissue radiographs gave images for a soft tissue mass at right neck (Figure 3).
Figure 3. Patient’s antero-posterior (a) and lateral (b) neck soft tissue radiograph.

Laboratory findings revealed moderate anemia, leukocytosis, thrombocytosis, metabolic acidosis, decreased oxygen saturation, also increase in ureum and creatinin serum.

We performed surgical intervention for the maxillofacial abscess consisted of extraoral incision and drainage as well as extraction of the mandibular right third molar, we found pus about 50 cc (Figure 4). Tracheostomy, incision and drainage of retropharyngeal abscess supposed to be performed by ENT department, but the patient refused.

Figure 4. Pus aspiration for bacterial culture resistention and sensitivity (a), incision and drainage (b), tooth extraction (c).

For inpatient care we managed this patient with fluid resuscitation and administration of ceftriaxone 2x1 gr, metronidazole 3x500 mg, ranitidine 2x50 mg, and antrain 3x500 mg intravenously, also nutritional support with soft diet 1800 Kcal/day, protein 1 gram/Kg/day, carbohydrate : fat ratio = 70:30%. We also monitored vital signs, any signs of worsening upper airway obstruction, the patient’s urine output, her ureum and creatinine serum level by serial laboratory examination, and also pus production. ENT department planned to perform tracheostomy and incision drainage for retropharyngeal abscess, but the patient still refused.

On the first day after surgery, we performed neck soft tissue radiographs re-examination to reevaluate airway column and the extent of retropharyngeal abscess. Compared with the results of previous emergency radiographs examination, this radiographs revealed laryngeal and pharyngeal airway column within normal limit, widening of retropharyngeal and retrolaryngeal space at C1-4 level (Figure 5). Clinically there was no any sign of worsening upper airway obstruction, there was no inspiratory stridor, respiratory rate was 17x/mnt. We did fluid resuscitation for next 18 hours as much as 65 drops/minutes of crystalloids, we also replaced the analgesic to antrain 3x500 mg intravenously as consideration of the patient’s kidney.
Figure 5. Patient’s antero-posterior (a) and lateral (b) neck soft tissue radiographs 1st day after surgery revealed laryngeal and pharyngeal airway column within normal limit.

We found improvement in AKI condition for this patient, which is decrease in serum creatinine as well as increase in urine output since we did fluid resuscitation and nutritional support for this patient following the incision and drainage that had previously been done and tooth extraction as source control.

**DISCUSSION**

Left untreated or not properly managed odontogenic infection can cause spreading into facial spaces. In this case, facial spaces infection were caused by mandibular right third molar infection. Spread of infection started through right submandibular abscess which then spreaded into right buccal space. Besides that, submandibular abscess originated from mandibular third molar infection can spreads contiguous into pharyngeal lateral space medially. Anatomically, lateral pharyngeal space have close approximation to retropharyngeal space, hence infection from lateral pharyngeal space can spreads into retropharyngeal space resulting in retropharyngeal abscess.

If this retropharyngeal infection is not treated immediately, it can potentially result in upper airway obstruction because of anterior displacement of posterior wall of pharynx, rupture of the abscess and aspiration of the pus into the lung resulting in asphyxiation, also can cause mediastinitis.\(^1,4,5\)

Grade I upper airway obstruction diagnosis due to retropharyngeal abscess was established through clinical examination as having inspiratory stridor accompanied by mild suprasternal retraction without infraclavicle, epigastric, and intercostal retraction. Upper airway obstruction grading was based on Jackson’s classification. We performed AP and lateral neck soft tissue radiographs, revealed narrowing in airway column and widening in retropharyngeal space. This space was measured at C2 level, normally the retropharyngeal width at C2 level is 6 mm, whereas retrotracheal space measured at C6 level towards posterior pharynx soft tissue is not more than 20 mm.\(^1\)

This patient supposed to be performed tracheostomy under local anesthesia and incision drainage for retropharyngeal abscess under general anesthesia. Unfortunately, patient refused tracheostomy and incision drainage by ENT department, but she still survived. We did close observation in vital signs and any sign in worsening upper airway obstruction for five days, and there was no signs of worsening in upper airway obstruction. Through early diagnosis and antibiotic therapy, some reports indicate that 10% to 40% of retropharyngeal infections resolve with only medical management.\(^1\)

This patient also presented sepsis with blood pressure of 100/60mmHg, pulse rate of 102 beats/min, body temperature of 38.6° C, and respiration rate of 24 breaths/min due to oral and maxillofacial infection with WBC count of 25,600/mm³. However, the most severe manifestation of sepsis is diffuse peripheral vasodilation, which produces septic shock. The vasodilation that occurs during sepsis is believed to be caused by toxins produced by infecting organisms and release of vasoactive substances as
the result of the interaction between bacterial products and infected tissues, white blood cells, and platelets. The peripheral vasodilation produces a relative hypovolemia, impairing perfusion of vital organs, such as kidney.  

Sepsis-induced AKI is defined by the simultaneous presence both of the RIFLE/ AKIN criteria for AKI and the consensus criteria for sepsis and by the absence of other clear and established, non-sepsis related causes of AKI.

On the fifth day after incision, drainage, and tooth extraction patient asked to return home without consent. Patient went home with improvement in her AKI condition with SCr 0.73 mg/dL and urine output >0.5 /kg/h for 6-12 hours (Table 2), the infections and sepsis condition also subsides. We also suggested her to come to Oral and Maxillofacial Surgery outpatient clinic for follow up and control at Hasan Sadikin hospital.

This is a rare and unique case of oral and maxillofacial infections derived from odontogenic infection with kidney involvement. Although this is a rare case we must always be aware of this condition and do not neglect it, and not only focused on the oral and maxillofacial region itself.

CONCLUSION

In case of oral and maxillofacial infection, the involvement of distant organ should be investigated, because this conditions result in high mortality rate. Early diagnosis and prompt treatment are important and lead to better survival.
